

# AVIAN ZOOGEOGRAPHICAL PATTERNS DURING THE QUATERNARY IN THE MEDITERRANEAN REGION AND PALEOCLIMATIC INTERPRETATION

Antonio SÁNCHEZ MARCO\*

**SUMMARY.**—*Avian zoogeographical patterns during the Quaternary in the Mediterranean region and paleoclimatic interpretation.*

**Aims:** The main aim was to present an overview of the avian geographical distribution patterns in the Mediterranean region during the Quaternary.

**Results and Conclusions:** For this study seventy-two fossil sites located in the current Mediterranean region and in its peripheral fringe have been analysed. Most of the sites bear avian assemblages rich enough to offer an insight on the main features of local paleornithocaenoses. The approach of the steady Mediterranean refugia is used to explain the avian geographical distribution drawn from the Mediterranean fossil records. As a consequence, we increase the accuracy of our knowledge on the climatic changes during this period.

**Key words:** fossil birds, Mediterranean region, Neogene, paleoclimatology, Quaternary, Refugia Theory, Steady Mediterranean Refugia approach, zoogeography.

**RESUMEN.**—*Patrones zoogeográficos de las aves durante el Cuaternario en la región mediterránea e interpretación paleoclimática.*

**Objetivos:** La intención de este trabajo es ofrecer un estudio sintético sobre los patrones de distribución geográfica de las aves durante el Cuaternario en la región Mediterránea, destacando los descubrimientos de fósiles hechos durante las últimas décadas.

**Resultados y Conclusiones:** Para este fin, se aporta la información obtenida en 72 yacimientos repartidos por toda el área de estudio. Esto constituye un total de 89 asociaciones orníticas fósiles de la región del Mediterráneo (vease el Apéndice 1). La situación geográfica de estos yacimientos se puede ver en la Figura 1, mientras que en las Tablas 1 y 2 se puede conocer la posición cronológica de los mismos, que para algunos es aproximada. La mayor parte de estos yacimientos poseen asociaciones fósiles con suficiente entidad para aportar datos fiables sobre las paleornitocenosis locales. Existen suficientes evidencias que indican que los límites geográficos de las especies de aves han cambiado varias veces durante el Cuaternario. Además, se acepta que algunos de estos cambios no han sido causados directamente por cambios pasados en el clima. Como se observa hoy día, se han registrado rápidos movimientos dispersivos hacia la región del Mediterráneo de especies con distribución más septentrional. Estas irrupciones no se han registrado de forma clara en el Plioceno superior ni en las primeras fases del Pleistoceno. Con los datos obtenidos a partir de estos yacimientos, se puede concluir que la composición taxonómica de las aves en la región del Mediterráneo no ha diferido, en algunas zonas y durante algunos períodos, de la que debía existir en regiones más septentrionales de Europa, pero en otras zonas las comunidades orníticas no fueron análogas a ninguna otra que encontramos en la Europa actual. Se propone un modelo explicativo para interpretar la distribución geográfica que parece indicar el registro fósil, al que se ha denominado modelo de los refugios mediterráneos estables. Como consecuencia, se obtienen algunos rasgos de los cambios climáticos que han afectado a la región mediterránea durante este periodo.

**Palabras clave:** aves fósiles, Cuaternario, Neógeno, Modelo de los Refugios Mediterráneos Estables, paleoclimatología, Región mediterránea, Teoría de los Refugios, zoogeografía.

## INTRODUCTION

The scenario of a climatically unstable late Neogene is supported on several sets of evidences. The most precise among those may be the temperature changes recorded in the ice cores of the Antarctic and Greenland, as well as

the  $\delta O^{18}/O^{16}$  record on foraminifera from the oceanic bottoms. Periglacial tilt formations and deposits of loess in medial latitudes indicate that there were phases in which the north of Eurasia and North America were covered by an ice cap on several occasions. During these stages (stadials), tempered species took refuge

\* Departamento de Paleobiología, Museo Nacional de Ciencias Naturales-CSIC, José Gutiérrez Abascal 2, E-28006 Madrid, Spain. e-mail: antoniom@mncn.csic.es

in the most southern zones of their respective areas of distribution, or even further south. At the same time, the fossil record demonstrates the blossoming of immigrant species, which were adapted to the colder conditions.

The shifts of the geographical distribution of taxa as well as biocoenoses are explained by two major theories: the Dispersal theory (Simpson, 1965; Matthew, 1915) and the Vicariance theory (Croizat *et al.*, 1974). These theories have had different methodological developments, and are usually considered as alternative approaches. The Refugia theory does not contradict the isolation of populations secondary to the fragmentation of the territory, neither the dispersal of some taxa with the subsequent arrival into new areas.

The character of refuge assigned to the Mediterranean region (MR) during the Quaternary, especially during the last glacial phase (Würm), the role it played in the phylogenetic differentiation, as well as in the current west Palaearctic distribution of birds, have been the subject of a large number of studies. Many of them are summarized in Moreau (1954, 1972), Blondel (1985, 1987), Tyrberg (1991a, 1991b) and Moureaux-Chauviré (1993). Related to this, some species which are assumed to have different climatic and habitat significances since they display at present disjunct geographic areas, appear together in the same levels of several Pleistocene deposits in southern Europe. This phenomenon has been referred in the literature as «mixed faunas» and «non-analogue faunas».

The Refugia theory, applied to the Quaternary, does not propose that all speciations have taken place in ecological refuges, but tries to explain many differentiation events which contributed to the development of the modern biotas (Haffer, 1982). The Mediterranean Refugia theory (MRT) (Moreau, 1954, 1972), a particular derivation from the Refugia theory, has proved to be limited in its explanatory capacity. Moreover, an uncritical actualistic notion of the «indicator species» (a species that manifests by its presence the existence of certain environmental conditions) has overcome in fact the MRT, leading to misinterpretations. The Pleistocene avian assemblages from the south of Europe are, with few exceptions, characteristic of tempered climatic conditions, similar to the actual ones. Nevertheless, when the remains of currently northern breeding or resident species,

as the Snowy Owl *Nyctea scandiaca* or the Pine Grosbeak *Pinicola enucleator*, are found in outcrops of the south of the continent, even in fossil assemblages of Mediterranean type, it continues to be interpreted as a proof of regional cool conditions in the past. Thus, the notion of «indicator species», with the meaning of «local or regional conditions indicator» leads to misinterpretation of the paleoecological and paleoclimatical implications of the avian fossil record (Sánchez Marco, 1996). In this way, the indicator value of individual taxa prevails in the literature on the ornithological community character. The increasing number of studies of European Pleistocene avian localities modifies understanding of this period. Thus, this paper proposes an alternative interpretation: the Approach of the Steady Mediterranean refugia (ASMR).

The ASMR was outlined in Sánchez Marco (1996). It leans on avian community features and, as a second step, in the individual species composition. Thus, the ASMR emphasizes the necessity of using analytical and comparative approaches to paleornithological assemblages with current ornithocoenoses (Sánchez Marco, 1999a, 1999b). Therefore, there are several ecological patterns providing the guide to finding out as much the paleoclimatic characteristics as the configuration of the landscape in the past. Some of these patterns have been studied in mammals and birds, as the habitat spectra of the community (Fleming, 1973; Evans *et al.*, 1981; Sánchez Marco, 1999a, 1999b). The phenetic behaviour spectra have been used by Sánchez Marco (1999b). The ASMR attempts to apply in concrete terms the Refugia theory to the distribution of birds in the Mediterranean region during the Quaternary. It relies on the notion and description of the role of «Northern irruptive species» (see the paragraph «Material and methods»). Its main difference with the MRT (Moreau, 1954, 1972) consists of comprising the occurrence of Mediterranean avifaunas during the whole Quaternary in the south of the Mediterranean peninsulas, even in the cool phases.

#### GEOGRAPHIC AND CLIMATIC CONDITIONS IN THE QUATERNARY

The MR is the contact area between two of the largest continental plates: the Eurosiberian

and the African ones. This condition has led to very complex geological and paleogeographical histories (Maldonado, 1985). Tectonic movements of both plates in the early Oligocene drove to a closed sea in this area. Subsequent to the desiccation of great extensions of the Mediterranean sea at the fall of the Miocene, the Messinian episode from 5.7 to 5.3 Ma (= millions of years) (see Gautier *et al.*, 1994), the opening of the strait of Gibraltar decisively transformed the regional geography, determining important biogeographical changes in mammal faunas from both the continent and the islands (Moyà-Solà *et al.*, 1999; Alcover, 2000; Azanza *et al.*, 2000). Two other major biotic events which occurred at the end of the Neogene affected the mammal faunas in the western MR: the *Equus-elephant* event (Early Villafranchian, MN 16, ca. 2.7 Ma) and the Galerian mammal pulse (1.0 Ma) (Azanza *et al.*, 2000). These events are in accordance with two of the three major shifts to more arid and open conditions, occurred in Africa around 2.8 Ma, 1.7 Ma and 1.0 Ma and which are recorded in marine eolian deposits (DeMenocal, 1995). The Mediterranean Sea reaches a considerable extension and its influence on the climate constitutes one of the main features of this region, since the lands around it show more or less homogeneous climatic conditions. Faunistic successions in the western Mediterranean islands as well as mass extinctions episodes are the object of some works, such as Moyà-Solà *et al.* (1999), Alcover (2000) and Seguí & Alcover (1999).

A critical date in the recent history of the global climate is 2.7 Ma. This cooling episode in the Arctic hemisphere had begun towards 3.1 Ma (Raymo *et al.*, 1989; Raymo, 1991), causing the growth of the polar cap. Previously, the temperate periods were warmer than the present one and the cold periods were warmer than some later warm interstages. Until that date, it is likely that the continents of the Northern hemisphere were free of considerable masses of ice. Coinciding with the beginning of the Matuyama, approximately 2.4 Ma ago, the first event of massive formation of icebergs in the North Atlantic is well documented. Important amounts of materials transported by icebergs were deposited in the Atlantic Ocean (Shackleton *et al.*, 1984; Raymo *et al.*, 1989). It was the beginning of the first Cenozoic glaciation in the Northern hemisphere.

The marine sediments 2.7 Ma old document accused drops of the oceanic temperatures (Raymo, 1992; Raymo *et al.*, 1989). Since then, the oscillations between tempered and cold stages have acquired greater amplitude keeping a tendency towards a major cooling. From approximately 1.5 Ma, the thermal oscillations point to a rate of increasing amplification, exceeding themselves the previous extremes as much mild as cold. Comparing the values of  $\delta^{18}\text{O}$  in oceanic sediments of the present interglacial stage with those of the last one million and a half of years, only in six occasions were reached such high temperatures. This happens in interstadials 43 (1.2 to 1.3 Ma), 35 (~ 1.1 Ma), 31 (0.9 to 1 Ma), 11 (~ 0.4 Ma), 9 (~ 0.3 Ma) and (~ 0.13 Ma). In fact, the Holocene temperatures are surpassed in the four last ones. It is interesting to note that most interglacials did not reach as high thermal values as in recent times. At the other extreme of the oscillations, the lowest temperatures of the cold episodes also take place at the end of the Pleistocene. They are concentrated from approximately 0.5 Ma, and are episodes 16 (< 0.6 Ma), 12 (~ 0.4 Ma), 6 (~ 0.15 Ma) and 2 (0.02 Ma). A series of datings by the U/Th method in marine sediment grants to the Eemian interglacial a maximum span of 10 ka (= thousands of years), and between 1 and 2 ka to the substage 5e (Slowey *et al.*, 1996). The fast and short-duration climatic changes happened during the last interglacial and in the base of the Weichselian, as showed from the oxygen isotopes analysis of ice cores from Greenland, were interpreted as «artefacts» owing to changes of state at the deepest zone of the ice cap (Adkins *et al.*, 1997). Although these climatic changes could be coincident with the above mentioned observations on the faunal changes of rodents in Central European deposits (Horáček & Ložek, 1988).

During the Würm period, the highest peaks in the Iberian Peninsula were covered by glacial sheets (Uchupi, 1988). The loess accumulations stretched out from west of France to the east, along the edge of the southern end of the last European icecap (Horáček & Ložek, 1988). Currents of polar waters descended up to a latitude of 42°N during the Quaternary cool peaks, and the Gulf Stream was turned aside towards the southwest. The Iberian Peninsula was exposed to predominant winds from the west

(Uchupi, 1988). Warmer temperatures giving rise to the present warm interstadial are noted in high latitudes 18 ka BP.

## MATERIAL AND METHODS

The scope of this paper covers the Quaternary, although the lowest limit considered here is not the generally accepted 1.6 – 1.8 Ma (Aguirre & Pasini, 1985). The reason for this consideration is that this limit —as well as the divisions of this period— has been established on the shifts of mammal distributions (mainly in Europe) (for instance, Mein, 1976; Fahlbusch, 1976; Bruijn *et al.*, 1992; Calvo *et al.*, 1993), and these do not correspond to the changes of avian paleogeography. In this regard, **Higuuelas** (*ca.* 3 Ma) is the oldest locality in the MR with an association of avian taxa similar to the ones found during the Lower Pleistocene: the small passeriforms constitute an important fraction of the species assemblage; from 26 species present in **Higuuelas**, only one (new) species of *Palaeocryptonyx* seems not to go through the conventional limit of the Pleistocene; and it appears to be a *Corvus* of the *pliocenensis/antecorax* group (a typical corvid or corvids of the European Lower and Middle Pleistocene). The uppermost limit chosen for the present work is the Epipaleolithic (after the last main cool pulse).

For this study seventy-two fossil sites located in the current MR and in its peripheral fringe have been analysed. The African side of this region is still a vacuum territory for the paleornithology of the Quaternary. Where possible, fossil localities, geological layers or sedimentary complexes providing rich avian assemblages have been chosen in order that they can approach to a certain extent the paleoclimatic and paleoenvironmental conditions. This comprises a total amount of 89 avian assemblages (Appendix 1). Some of the fossil associations used in this work can be excluded as samples of paleornithoceanoses, since these constitute clear cases of associations containing the recent introduction in Europe of *Gallus* (**Bacho Kiro, Fontéchevade, Ibex**), where the mixture of layers is in no doubt. Despite this, such localities have been chosen due to the scarcity of fossil assemblages in some areas or to cover some time spans. They are only used to illus-

trate the presence of individual species. The data have been taken directly from the original works to avoid possible mistakes, with the exception of one or two cases that are pointed out. Some publications have not been considered for this paper since they contain obvious mistakes. All the authors and publications do not merit the same degree of confidence; however, the aim of this paper is not to review the published material. Some of the taxonomical identifications and the chronological attributions should be re-examined.

The geographical situation of the localities is given in the map of Figure 1. The sites have been listed in two chronological tables (Tables 1 and 2), although their respective positions are approximative for many of them.

### *Non-Mediterranean irruptive species*

Some high dispersive species, which are nowadays distributed along northern Eurasia are recorded in Quaternary localities of MR. A case repeatedly noted in the literature is that of the Snowy Owl *Nyctea scandiaca* (Lambrecht, 1933; Brodkorb, 1971; Boev, 1998a). According to their respective current distributions, such species are considered herein as irruptive in the whole or a part of the MR during the Quaternary (Appendix 2). In Appendix 1 each irruptive species is highlighted with an asterisk when the fossil locality falls in the corresponding «area of irruption» of that species (see Appendix 2). The current ranges of the Pygmy Owl *Glaucidium passerinum* and Tengmalm's Owl *Aegolius funereus* cover approximately the northern border of the MR. When these species appear in localities near the limits of the MR, they are not considered as irruptive into it, but as punctuating the spreading of Eurosiberian climatic conditions.

### *Non-Mediterranean low-dispersive species*

The grouses (*Lagopus* sp., *Tetrao* sp., *Lyrrhus* sp., *Bonasa* sp.) are a low-dispersive group of birds whose respective geographical distributions are fairly outside the MR (Cramp, 1998). In this paper it is assumed that those species were not included in the past components of Mediterranean paleornithoceanoses

neither. Thus, their presence in Mediterranean localities may be understood as: (a) the fossil association was deposited under non-Mediterranean conditions or (b) it is a mixture of paleornithocaenoses from periods with different climatic conditions. These species are underlined in Appendix 1.

#### *East Mediterranean surviving species*

Appendix 3 lists the species which are nowadays distributed along the east part of the MR, but that are also recorded in fossil localities from the west part. In Appendix 1 these taxa are highlighted with an asterisk when appear in localities from the west area of the MR.

#### SURVEY OF THE FOSSIL LOCALITIES

##### *Last Pliocene and Early Pleistocene*

The Iberian locality of **Higuerales** (MN 16) (Bruijn *et al.*, 1992) has been dated between 3.18 and 3.46 Ma (Bonadonna & Villa, 1984) and to 3.2 Ma (Aguirre & Morales, 1990). The presence of several shallow lakes, combined with regional volcanism, provided suitable environments for the preservation of a large sample of the local paleornithocaenoses. In the species assemblage yielded by this outcrop, the larger ecological group was constituted by aquatic birds: Slavonian Grebe *Podiceps auritus*, Black-necked Grebe *P. nigricollis*, Whooper Swan *Cygnus cygnus*, goose sp. *Anser* sp., shelduck sp. *Tadorna* sp., Greater Scaup *Aythya marila*, White-headed Duck *Oxyura leucocephala* and Smew *Mergus albellus*, as well as for those species also linked to aquatic environments: Grey Heron *Ardea cinerea*, Black-crowned Nightjar *Nycticorax nycticorax*, Little Bittern *Ixobrychus minutus*, Glossy Ibis *Plegadis falcinellus*, Common Sandpiper *Actitis hypoleucos* and Meadow Pipit *Anthus pratensis*.

The finding of *C. cygnus*, *A. marila* and *M. albellus* constitutes an unexpected event concerning the age and geographic situation documented by this locality. At present, they are breeding species in northern zones of Eurasia, and are rare in Iberian territory. In the case of the swan, this only appears with occasion of

hard winters (Díaz *et al.*, 1996). Contingents of these three species move during the winter, not only to Central Europe and north of France, but also to more southern latitudes, such as the Balkan Peninsula and Anatolia.

**Montoussé 5**, dated to the Upper Pliocene, in the northern side of the Pyrenees, has yielded a small quantity of bird remains, including *Corvus pliozaenus* and *Palaeocryptonyx* sp. (Clot *et al.*, 1976). The fauna is characteristic of temperate conditions and of forest environments. Each of these mentioned taxa appear in two respective sites in Mallorca (Balearic Islands), *Palaeocryptonyx* sp. in **Ca na Reia** (Upper Pliocene), together with a small quantity of other taxa (Alcover, 1989), and *C. pliozaenus* in **Pedrera de S'Onix** (Plio-Pleistocene) (Mouler-Chauviré *et al.*, 1977). Moreover, this locality situated near Manacor has yielded a relatively large collection of birds (Mouler-Chauviré *et al.*, 1977; Mouler-Chauviré in Alcover *et al.*, 1981), most of them from woodland habitats, and two irruptive taxa *Cygnus* cf. *cygnus* and *Bucephala* cf. *clangula*. Further taxonomic revision of this fauna by Seguí (1996) has not changed its paleoenvironmental implications.

Although it is partially outside of the chronological framework of this paper, it is worth while mentioning *Tyto balearica*, a paleospecies of barn owl widely distributed in the West Mediterranean area throughout a notable span of time, which was classified on fossil material from three Balearic localities (**Canet**, **Pedrera de S'Onix** and **Binigaus**) dated on the Plio-Pleistocene boundary (Mouler-Chauviré *et al.*, 1980). This species was later identified in some older sites in France and Spain: **Layna** (Early Pliocene, MN 15), **Sète** (Early Pliocene, MN 15), **Balaruc II** (Late Pliocene, MN 16), **Casablanca 1** (Late Pliocene, MN 17) (Mouler-Chauviré & Sánchez Marco, 1988; Mouler-Chauviré, 1995; Sánchez Marco, 1995a), **Aljeyer B** (Late Miocene, MN 12) (Cheneval & Adrover, 1993), **Valdecebro 5** (Late Miocene, MN 12), **Layna** and **Moreda** (Late Pliocene, MN 16) (Sánchez Marco, 2001). This owl has been also identified in two Middle Pleistocene sites: **Castiglione 3 CG** (Mouler-Chauviré in Salotti *et al.*, 1997; Mouler-Chauviré *et al.*, 1997) and probably **Punta di Calcina** (Corsica) (Pereira *et al.*, 2001). Moreover, remains from the complex of outcrops of **Gar-**

**gano** (Early Pliocene, Southern Italy) have been attributed to this species (Milíkovsky, 1998).

**Varshtets** fossil locality is a ponor situated near the homonymous town, in northwest of Bulgaria. It has been assigned to the Late Pliocene, MN 17 (Boev, 2002). Its very rich association of birds has led to a large bibliographic production (Boev 1995, 1997, 1998b, 1998c, 1999a, 1999b, 1999c, 1999d, 1999e, 2000a), summarized in Boev (2002). The specific composition of this fauna is sufficiently different from the Pleistocene ones to establish confident comparisons. There have been no findings of *Geronticus*, *Tyto balearica* or *Palaeocryptonyx*. The presence of *Lagopus* and *Tetrao* in the Balkan Peninsula is constant along the whole Quaternary.

Located in the north of the Dead Sea Rift (Israel), and near the Tiberias or Kinneret Lake, there is the site of **Ubeidiya** which is composed of more than sixty archaeological horizons of an age of c. 1.4 Ma. This lower Pleistocene site reveals a complex geological structure in which tectonic movements have tilted the deposits. The cultural remains are assigned to the Acheulian tradition (Bar Yosef & Goren-Inbar, 1993). As evidenced by the abundant aquatic species (Tchernov *fide* Tyrberg, 1998), the outcrop was situated close to an area of marshes and bodies of water.

**Quibas** site has an age between 1.0 and 1.3 Ma after the rodents' association. No avian wintering or northern species have been found in this outcrop. The group of taxa, where most of them are related with masses of water and parkland environments, points to moister climatic conditions than present ones (Montoya *et al.*, 1999, 2001).

The early Pleistocene site of **Victoria** is located on the southern Iberian coast. Some remains of swan (*Cygnus cf. olor*) also appear in this outcrop, which should be considered as a wintering species. Hedge Accentor *Prunella modularis* is currently a resident passeriform in mountain areas in the half north of the Iberian Peninsula, but during the winter this bird makes short displacements towards the south or to lower levels throughout its distribution. Black-headed Bunting *Emberiza melanocephala* is not resident in the western zone of the Mediterranean of today and breeds in the Balkan region and Anatolia.

The rich deposit of **Dursunlu** is placed in the eastern extreme of the MR, in the Konya basin, near Llgin (southern Anatolia), which is attributed an age between 0.9 and 1 Ma (Guleç *et al.*, 1998). Louchart *et al.* (1998) offer a list of 50 species, the immense majority of which is of aquatic habitats. The set of taxa of resident and breeding species corresponds to tempered climatic conditions, with the presence of numerous wintering birds.

The study of **Elefante** site is still incomplete. This locality belongs to the **sierra de Atapuerca** karstic infillings complex, situated in the northern plateau of the Iberian Peninsula. The lower layers contain a rodent assemblage from ca. 1 Ma. Bones from *Corvus antecorax* and White-tailed Eagle *Haliaeetus albicilla* are the most abundant ones (Rosas *et al.*, 2001). There are no fossil remains fairly attributable to wintering species.

There are other rich fossil localities in the Iberian Peninsula in chronological range between 1 Ma and the beginning of the Middle Pleistocene. **Huéscar 1** is a fossil locality situated in a present-day arid zone in the southern Iberian inland. The avian taxa are, with little exceptions, aquatic ones, most of them, anatids (Sánchez Marco, 1989). Two of the species that appears here, Common Scoter *Melanitta nigra* and Red-breasted Merganser *Mergus serrator*, currently are not inland wintering species (Díaz *et al.*, 1996). This behaviour is associated with periods of storms and rough weather on the coasts.

The Lower Pleistocene **Dolina** outcrop belongs also to the **Atapuerca** complex. The layer 6 (TD-6) is older than 0.8 Ma and has yielded one of the richest avian assemblages in Iberia, where open country species constitute the best represented group, followed by bushland biotope and inland water birds (Sánchez Marco, 1999b). On the other hand, resident species reach the highest values, especially those residents in the modern Eurosiberian zone of the Iberian Peninsula. Wintering and breeding taxa have a comparatively low incidence. The occurrence in TD 6 of such taxa as *Anas*, *Melanitta*, *Porzana* and *Cinclus* provides evidence for the presence of a body of water nearby, larger than the modern-day Arlanzón brook that runs about 3 km from the outcrops. In conclusion, the avian remains from this layer point to three main ecological traits: (a) the existence of

a pool, lake or slow river in (b) an open country type of habitat, and (c) that climatic conditions were similar to modern Iberian winters or that most fossils were deposited in the cave during the winter season (Sánchez Marco, 1999b).

### Middle Pleistocene

The site **Orgnac 3**, at Orgnac-L'Aven (France), was constituted by the fulfilling of a doline. The stratigraphic profile shows 19 layers, among them the layer i is the richest in avian remains. For this reason, as well as for the occurrence of *N. scandiaca*, the fossil assemblage from this unit has been chosen for the present study. The avian bones were studied by Mourer-Chauviré (1975a). After the rodent association, Jeannet (1974 *fide* Mourer-Chauviré, 1975a) attributed the layer i to the Mindel-Riss phase. An important fraction of the species are tree-dwelling birds, and it is also remarkable the abundance of galliforms. The rodents should indicate a temperate and dry climate (Chaline, 1972, *fide* Mourer-Chauviré, 1975a).

The Aven 1 of **La Fage** is a karstic infilling situated near Noailles town (France). It has yielded one of the largest list of species in the Middle Pleistocene, with more than 100 taxa (Mourer-Chauviré, 1975b; Mourer-Chauviré *et al.*, 2003) distributed along the whole stratigraphy (Mourer-Chauviré & Philippe, 1972). Avian remains are more abundant in the stratigraphic unit CO (Mourer-Chauviré, 1975a), a subdivision of the layer 5. The climatic conditions for this layer have been interpreted (Mourer-Chauviré, 1975b; Mourer-Chauviré *et al.*, 2003) as being slightly colder than today, but with colder and warmer periods, because terrestrial gasteropods, micro- and macromammals as well as some birds from this layer would indicate temperate climatic conditions, and, on the other hand, some other bird species are tied to cold climates.

**Ambrona** and **Torralba** are two localities 3 km apart, both related to acheulean occupations (Santonja, 1989; Santonja & Vila, 1990). The ten avian species found here are aquatic ones (Sánchez Marco, 1990, 1999c). With the exception of two rallids (Purple Swamphen *Porphyrio porphyrio* and *Fulica cf. atra*), the remaining species were identified as wintering species. Also attributable to this age and loca-

ted in the middle of Iberia is **Áridos 1**, an anthropic deposit formed in one bank of the Jarama River. The best ecological group represented here is the one tied to woodlands and forests. Likewise, there are aquatic and open country species (Mourer-Chauviré, 1980).

**Castiglione 3** is a karstic cavity in the Oletta massif (north of Corsica). The deposit **Castiglione 3 CG** is a fissure that contains a large quantity of fossil remains. It has been attributed to an age of 350 ka (Salotti *et al.*, 1997). The identification of the birds is owed to Mourer-Chauviré (*in Salotti et al.*, 1997). This Middle Pleistocene site records one of the last occurrences of *T. balearica*, which appears with Barn Owl *T. alba*. The major part of the collection is composed by diurnal and nocturnal raptors, with two insular paleoendemisms.

**Fontéchevade** cave is in the middle west of France, near Montbron town. The fossil assemblage corresponds to a woodland habitat type (Mourer-Chauviré, 1975a). It contains characteristic Mediterranean avian taxa as well as non-Mediterranean ones, and one or two species which occurrence could be interpreted as the result of invasions from north Europe.

The site known as **Galería** also belongs to the **Atapuerca** complex. The three stratigraphic units containing the highest diversity of avian species are, from top to bottom: TG11, TG10A-TN7 and TG10B-TN6 (Sánchez Marco, 1995b, 1999a). These units are younger than an immediately below stalagmitic crust dated to  $317.6 \pm 60$  ka (ESR, Grün & Aguirre, 1987), and older than the crust immediately above dated to  $211 \pm 32$  ka (ESR, Falguères, 1986) and  $177.3 \pm 23$  ka (ESR, Grün & Aguirre, 1987). The filling of this cavity does not coincide chronologically with the ones of **Dolina** and **Elefante** (Made *et al.*, 2003).

The bird remains found in the TG10B-TN6 and TG10A-TN7 units, compose habitat and phenetic spectra which are characteristic of humid zones with open lands. They correspond to zones in which the fauna acquires its greater diversity in the wintering periods. Some considerable forest masses might have existed, as can be deduced from the passeriforms related to landscapes with shrubs and trees. There is no evidence to affirm that these areas, with more or less open forests, constituted one of the main elements of the surroundings. The habitat and phenetic spectra of the superior stratigraphic

unit, TG11, points to reductions of the temperature and the humidity for that period, in comparison with the condition of the underlying layers. During the corresponding time interval the bodies of water continued to determine the local communities of birds and it seems that a regression of the forests took place. One trait of the landscape recorded in the Early and Middle Pleistocene of Atapuerca could be the existence of a humid zone that extended to the foot of the mountain range of Atapuerca. This humid zone was made up of backwaters (pools or fluvial sections of slow-flowing waters) and streams. It changed in extension on several occasions and, probably, in depth. It seems that this region was a wintering area which was very important in the periods corresponding to lower layers of **Elefante** and upper ones of **Galería** (Made *et al.*, 2003).

The **Lazaret** site is a 40 m long cavity, located in the Boron mountain near Nice and 100 m from the current coastline. During the Middle Pleistocene its distance from the sea was around 500 m (Vilette, 1993). The stratigraphic unit C.III is observed in the profile at the entrance of the cave. These sediments were deposited before the formation of a stalagmitic crust dated between 125 and 70 ka BP (Falguères *et al.*, 1992). Thus, **Lazaret C.III** has been attributed to an age of 150 to 125 ka BP, OIS 6. All the species showed in Table 1, except *Cinclus cinclus*, appears in the first layers of this stratigraphic unit (Vilette, 1993: Table XII). The avian assemblage corresponds to a forest area with inland humid zones. The nearness of the sea is also noted in the fossil remains of birds. Some years before the work on the unit C.III, Mourer-Chaviré (1964, 1975a) studied two other units of this cave: Locus VIII and some layers from the bottom of the cavity. Both infillings (**Lazaret Locus VIII** and **Lazaret bottom**) are considered to have been deposited during a large span of time during the Riss interval (Mourer-Chauviré, 1975a). Thus, none of both avian associations may be understood as samples of individual avifaunas, but as a mixture of different ones. In spite of this, their taxonomical compositions and their respective representation of habitats are very similar to those of the unit C.III, although the latter encompasses a shorter interval. These three associations include typical Eurosiberian and Mediterranean taxa, particularly the corresponding

to Locus VIII and C.III. A sharp difference in this one is the appearance of several northern irruptive species as well as *H. albicilla* and Pallid Harrier *Circus macrourus*, today restricted to more eastern areas.

Therefore, either the southern coast of France suffered fluctuating climatic conditions during the cool phases of this period or there was a strip alongside the coast with a real «mixed» ornithofauna with no parallel today.

Approximately in the middle of the Italian Peninsula, **Quartaccio** quarry (Vitinia, Rome), records an assemblage from the Vitinia Formation (Bedetti, 2001). The corresponding avian list of the Appendix 1 is the result of a revision by Bedetti (2001) of previous works. Most of the species correspond to aquatic-dwelling birds. The occurrence of the Eider *Somateria mollissima* should be considered as an irruptive species into this region.

The avian remains from **Spinagallo** cave, near Siracusa (southeastern Sicily), were studied by Pavia (1999). It contains a fossil association dated of about 500 ka BP (Bada *et al.*, 1991), and composed of a large list of Mediterranean taxa. The degree of isolation during the period represented by this assemblage seems to have been quite reduced.

Among the five Pleistocene faunal complexes described in Sicilian localities, one of them, ***Elephas mnaidriensis* Faunal Complex**, from the Middle Pleistocene, has yielded an important avian assemblage (Pavia, 2001). Three outcrops contribute to the avian collection: **K 22**, **Acquedolci** and **Contrada Fusco** —the former studied by Cassoli & Tagliacozzo (1996)—. The assemblage of birds shows the typical traits of the Mediterranean insular avifaunas (*sensu* Alcover *et al.*, 1992) but reveals a reduction of the degree of isolation (Pavia, 2001). The Goosander *Mergus merganser* seems to be a northern irruptive species.

#### Upper Pleistocene

**Torre in Pietra** locality is in the province of Rome and was studied by Cossoli (1978). The layer m, with a pre-würmian lithic industry, has a Mediterranean assemblage of birds, with a high proportion of water species.

In the north of Spain, in the area today included in the Eurosiberian region, **Valdegoba**

TABLE 2

cave whose sediments were deposited during the Mousterian period (Díez *et al.*, 1989), offers an avian association with Mediterranean as well as Eurosiberian characteristic species. Three northern irruptive species are recorded. Two more reduced assemblages, but with similar features to **Valdegoba** are the Italian localities of **Radice** valley (Bidutti *et al.*, 1967) and **Carnello** (Segre *et al.*, 1984), both situated near Sora village and with some Mousterian tools collections.

The Upper Pleistocene deposits from **Cova Nova** locality (Capdepera, Mallorca Island) have yielded a large sample of a Mediterranean insular avifauna (Florit & Alcover, 1987; McMinn & Alcover, 1992). The occurrence of the Bullfinch *Pyrrhula pyrrhula* in the Balearic Islands has to be considered as a case of irruption of a northern species. Another typical Mediterranean assemblage was collected at the locality of **Es Pouàs** (Florit *et al.*, 1989). This karstic cavity, where there are no remains of irruptive taxa, is situated near Santa Agnès de Corona (Eivissa Island).

The fossil remains from **Bacho Kiro** cave were studied by Bocheński (1982). This locality from the Stara Planina region (Bulgaria) shows an assemblage characteristic of temperate to mild conditions. The presence of Ptarmigan *Lagopus mutus* would lead to assumption of some relatively cool temperatures, although this species seems to have occurred in forest zones in the Late Pleistocene (Bocheński, 1974).

**Cau d'en Borrás** is a cavity on the east coast of Spain, near Oropesa town as well as the current sea line, in spite of which the only species recorded which is connected with the sea is *Haliaeetus albicilla*. The fossil assemblage is characteristic of open Mediterranean habitats. It is important to point out that the closeness of the sea does not seem to have any consequence in the avian fossil record at the locality.

Gibraltar has a big number of karstic cavities, a lot of them with a valuable Pleistocene record. **Gorham's** cave is situated close to the south end of this small Peninsula. The fossil remains from this site were studied by Eastham (1968). Two avian assemblages are the richest: one from layers B and D attributed to Würm III (*ca.* 29 ka BP) another from layers K and U, attributed to Würm I. The former is an unbalanced sample of the corresponding local

avifauna. Most of the taxa are marine species, raptors and rock inhabitants. The assemblage from layers K and M is also of Mediterranean type but records the presence of some northern irruptive birds.

**Devil's Tower** shelter was situated —it was dismantled some time ago— near the isthmus of Gibraltar. Its faunal remains were identified by Bate (1928). The avian association is very similar to the ones mentioned for **Gorham's Cave**. Not far from here, between both localities and about 250-300 m a.s.l., there is **Ibex** cave, whose fossil association, studied by Cooper (2000) represents also a Mediterranean ornithofauna. The dates of **Ibex** cave (Rhodes *et al.*, 2000) support a Late Pleistocene age for this cavity but later than **Gorham**.

With the exception of Great Auk *Pinguinus impennis* and northern irruptive species, the taxa recorded in the Gibraltarian localities are the same ones that are currently observed at this migratory point (Finlayson, 1992).

**Gegant** cave is situated on the coast of Barcelona, in the Garraf massif. The assemblage of the layer II indicates, as in other cases, open areas with climatic conditions typical of the Mediterranean region.

**Arbreda** cave is near the Serinyà village, in a zone of the north of the Iberian Peninsula with intense processes of travertine formation and karstification (Garcia, 1995). The avian finds of this outcrop have been studied by Vilette (1983) and Garcia (1995, 1997). The largest fossil assemblages correspond to the stratigraphic units: Mousterian, Aurignacian (dated to  $25,830 \pm 400$  aBP —years before present—) and Gravettian (dated to  $20,130 \pm 220$  aBP) layers by Garcia (1995) and Aurignacian layers by Vilette (1983). All the assemblages are typical of the current Mediterranean region. In the Gravettian association, Garcia (1995) attributed one of the finds to *Lagopus* sp., but this fact does not determine the meaning of the whole avian association. The appearance of *P. enucleator* in the Upper Paleolithic layers of **Arbreda II** (Vilette, 1983) is important.

**Romaní** site is a rock shelter built in a travertine formation and located just in Capellades village, northeast Iberia. The stratigraphic unit II has been dated between 40-44 ka BP (Bischoff *et al.*, 1988). It contains a small sample of the corresponding ornithofauna. A noticeable feature is the occurrence of *P. enucleator*.

In the Languedoc region (south of France), the Mousterian layers from **Hortus** cave have provided a collection of fossil birds studied by Mourer-Chauviré (1972, 1975a). It is a typical Mediterranean assemblage with no record of characteristic Eurosiberian species. Ten kilometres from **Hortus** there is **Salpêtre** cave (Mourer-Chauviré, 1975a), this likewise containing Mousterian and Upper Paleolithic layers. The avian assemblage from the Mousterian layers from the latter show the occurrence of Mediterranean and Eurosiberian species, something already seen at other localities from this area. The same features can be observed in layers 1a and F1 (transition Dryas 3 – Preboreal) from **Salpêtre** cave, studied by Vilette *et al.* (1983).

**Coscia** localities are situated in the north end of Corsica Island. Two fossil avian deposits are distinguished (Bonifay *et al.*, 1998): **Coscia (rock shelter South)**, from the early Würm, and **Coscia cave**, *ca.* 60 ka BP. Both avian assemblages are typical of western Mediterranean islands. In the shelter South record there is evidence of irruption of northern species.

Cassoli (*in* Bulgarelli, 1972) identified the fossil birds from **Torre Nave** cave. This site is situated on the southern coast of the Italian Peninsula, in Cosenza. Unexpectedly, there are not any marine species in the avian assemblage. Nor northern irruptive species are.

Near the village of Remoulins, not far from Nîmes (southern France), is **Salpêtrière** shelter. The stratigraphic complex CG5-SLC4 (corresponding to layer 14a) has yielded the richest avian association of this site. It has been attributed to the early Aurignacian and dated of  $28,180 \pm 1,000$  aBP (Vilette, 1983). The presence of aquatic species is explained by the closeness of the Gordon River, but the record of low dispersive Eurosiberian species as well as northern irruptive birds, together with the absence of typical Mediterranean taxa points to Eurosiberian paleoenvironmental conditions.

**Fumane** rock shelter is located in the region of Veneto, north Italy, close to the Alps range. Therefore, it is outside of the Mediterranean region. The avian remains were studied by Cassoli and Tagliacozzo (Bartolomei *et al.*, 1992; Cassoli & Tagliacozzo, 1994). The Mousterian collection is very scarce, but the Aurignacian one constitutes a relatively good sample of the local avifauna. It is characteristic of the Euro-

siberian region with presence of some irruptive species from north Europe.

At the west end of the Mediterranean region, **Figueira Brava** cave (Mourer-Chauviré & Antunes, 1991, 2000) is situated south of Lisbon, on the coast of the Setubal Peninsula. The composition of its Mousterian assemblage is highly influenced by the closeness of the site to the sea. The avian local fauna was of Mediterranean type with a high proportion of aquatic taxa, two of them might be considered as northern irruptive species.

Boev (1994) studied the avian remains from **Temnata** cave, near Karlukovo village, and situated in the middle west of Bulgaria. The largest avian assemblage comes from the layer 3d, dated of  $28,900 \pm 1,100$  aBP. It is not a very rich layer in fossil birds, but the corresponding association of taxa would fit better with a Mediterranean avifauna. On the other hand, the layer 3a, dated of  $13,600 \pm 200$  aBP, contained an avian assemblage characteristic of Eurosiberian conditions. None of these assemblages record the occurrence of northern irruptive species.

**Sandalja I** and **Sandalja II** caves are situated on the northern coast of Croatia. Their avian remains have been the subject of some works by Malez (*fide* Tyrberg, 1998). The layer d of the former has been attributed to the Gravettian lithic period (Würm 3) whereas the layer E of the latter to the Aurignacian (with a date of  $23,540 \pm 180$  aBP). Both fossil assemblages are characteristic of woodland habitats, although the presence of *Lagopus* in **Sandalja I** could be understood as an indicator of a cooler phase, in spite of there not being any record of any northern irruptive taxa in such a large variety of aquatic habitat species. The same author (Malez *fide* Tyrberg, 1998) has studied the birds from **Vindija** cave, situated in the north of the country. Its largest assemblage is dated at *ca.*  $26,970$  aBP (Würm 3) and corresponds to the layer E + F, which is attributed to the Aurignacian. Thus, the above-mentioned assemblages from these three Croatian sites are chronologically very close one another. Moreover, the paleoenvironmental features implicated by these local associations are practically the same.

The locality of **Ohalo 2**, in the Galilee region (Israel), has a rich record from the Early Epipaleolithic (Simmons & Nadel *fide* Tyrberg,

1998), dated of about 19,400 aBP. The assemblage corresponds to a typical eastern Mediterranean avifauna, but there are six northern irruptive species recorded.

The avian remains from **Bois-des-Brousses** shelter were studied by Vilette (1983). This locality is close to the Hérault River, 25 km from Montpellier. The layer 2B (attributed to the Solutrean) contains a non-Mediterranean fossil assemblage and the uncertain presence of a northern irruptive species (cf. Great Snipe *Gallinago media*).

In the middle of the Iberian Peninsula, the rock shelter named **Jarama II** has yielded an avian assemblage attributed to the Early Magdalenian phase (Jordá, 1993; Adán *et al.*, 1995) which is clearly of non-Mediterranean type, although there is no record of irruptive species from north Europe.

**Castiglione 3 PL** is an Upper Pleistocene karstic infilling rich in avian remains in the above-mentioned **Castiglione 3** complex. Sediments from PL fissure are dated of about 15 ka BP (Salotti *et al.*, 2000). The corresponding avian assemblage is, as for the CG fissure, also typical of Mediterranean islands, with the exception of the presence of *Alectoris*.

**Palidoro** quarry is situated near Rome. It yielded a reduced avian association, which was attributed to the Upper Paleolithic period (Cassoli, 1977). The taxonomical composition of this association is of Mediterranean type.

**Romains** cave at Pierre-Châtel, near Virignin village (French Alps), is not today —and probably never was— in the Mediterranean region. Its Magdalenian avian association (Desbrosse & Mourer-Chauviré, 1973; Mourer-Chauviré, 1975a) is consequently characteristic of a woodland habitat under a fresh climate. The high percentage of aquatic species is explained by the nearness of the Rhone River to the cave. The Snowy Owl appears in the record of this cavity.

Dimitrijević *et al.* (2000) have studied the Epigravettian rock shelter of **Trebački**. This locality is near Berane village, in Yugoslavia. The avian assemblage is characteristic of the Eurosiberian region. There is also the record of *P. enucleator*.

The fossil birds from **Nerja** locality—a cave situated near the homonymous village, in the south of Spain, approximately 1 km from the current sea line (Jordá, 1986)—have been the

subject of several works. The most informative assemblages correspond respectively to: Epipaleolithic (Boessneck and Driesch, 1980; Hernández Carrasquilla, 1995; Tyrberg & Hernández Carrasquilla, 1995), Magdalenian (Eastham, 1986) and Upper Paleolithic layers (Hernández Carrasquilla, 1995). The aquatic species constitute the largest group in every assemblage, being the small passeriforms absent or not identified.

**Kozarnika** cave is located near the town of Bologradchik, north-west Bulgaria. The avian finds were collected in the cultural layers III and IV, which have been attributed to the Gravettian (26 to 19 ka BP; Boev, 2001). The fossil material was accumulated into the cavity by nocturnal raptors, most probably by *Bubo bubo* (Boev, 2001). The association of birds shows a large representation of Eurosiberian species. It implies woodland or forest habitats with no Mediterranean conditions. The Snowy Owl appears as an irruptive immigrant.

**Arene Candide** is one of the richest Pleistocene avian localities of Europe. The fossil birds from this cave, situated in the Ligurian coast of Italy, were studied by Cassoli (1980). Sediments from the Upper Paleolithic, with a thickness about 3.8 m, show an avian assemblage with twelve northern irruptive species, as well as typical low dispersive Eurosiberian and Mediterranean taxa. This fact may be the result of a mixture of layers—or avifaunas—or, on the contrary, to represent the reality during the Upper Pleistocene in this area.

The site of **Mas-d'Azil** consists of a large cave situated in the French Pyrenees, 30 km from Foix town. The avian finds, studied by Vilette (1983), come from the cavity named «galerie rive droite». All the fossils were collected in the Magdalenian layers ( $13,400 \pm 1,000$  and  $13,200 \pm 110$  aBP) (Vilette, 1983). As it can be expected by the geographical situation of the locality, the avian taxa imply a non-Mediterranean climate. The Snowy Owl is recorded together with the Eagle Owl. The same author (Vilette, 1983) studied the birds from **Cingle Vermell**, a shelter located near Vilanova de Sau village, northern Iberia. The avian assemblage of the Tardiglacial layers (dated to  $11,620 \pm 140$  aBP) is characteristic of Mediterranean conditions.

**Razhishkata** cave situated near Lakatnik station, Sofia district (Bulgaria), has a fossil

record from the end of the Pleistocene and probably of the transition to the Holocene (Boev, 2000b). The avian assemblage contains low dispersive species linked to a woodland habitat under Eurosiberian conditions.

The richest avian association of the final Upper Pleistocene was recovered from **Romanelli** cave (south of the Italian Peninsula), with two series of dates:  $11,930 \pm 520$  and  $9,050 \pm 100$  aBP (Cassoli & Tagliacozzo, 1997) and also  $10,640 \pm 100$  and  $9,980 \pm 100$  aBP, all of them for the formation Terre brune (upper part of the stratigraphical profile; Tagliacozzo & Gala, 2000). A large amount of water species, with clear evidences of human exploitation of anseriforms (Tagliacozzo & Gala, 2002), and raptors are recorded here, and some irruptive taxa among them.

**Cendres** cave is in the eastern coast of Spain, near Teulada village. It has yielded an unbalanced sample of the avian paleornithocenoses, identified by Villaverde *et al.* (1997), from the end of Magdalenian. The authors point out the possible presence of the irruptive Brent Goose *Branta bernicla*.

**Hayonim** cave, situated in the Galilee region of Israel, has some very rich collections of fossil birds related to Natufian period. The layer B, dated of 10.7 to 12.4 ka BP and studied by Tchernov (*fide* Tyrberg, 1998) as well as the sample studied by Pichon (*fide* Tyrberg, 1998) provide an exceptional insight to the local avifauna in this period. It is characteristic of the eastern part of the Mediterranean region and it is worthwhile mentioning that no northern irruptive species have been found in this very large fossil record, unlike those seen in **Ohalo 2**, the other Galilean locality.

**Fontbrégoua** locality is a large cavity situated near Salernes village, about 60 km from Toulon, France. The most important avian collection come from the Epipaleolithic layer (50 to 53), with an infradate of  $8,400 \pm 110$  (layer 54) and  $7,600 \pm 100$  aBP (layers 50 and 51; Vilette, 1983). The very rich fossil assemblage of birds is characteristic of a zone under Mediterranean conditions, with a predominant woodland habitat. Eurosiberian indicator species are not recorded.

Mourer-Chauviré (1999) studied the Early Holocene fossil bird collection from **Akrotiri** locality. In spite of its modern age, these avian remains are the oldest known from Cyprus. The

small assemblage represents an insular Mediterranean ornithofauna with no occurrence of northern species.

Among the localities from Crete studied by Weesie (1988), **Liko** is the richest one by far. **Liko** cave is near Likotenaria village, on the northwest coast of Crete, in a cliff, a few metres above sea level. The fossil assemblage is a wide sample of an eastern Mediterranean avifauna, with insular endemisms, species of eastern distribution and one or two northern irruptive taxa (Tengalm's Owl *Aegolius funereus* and cf. *Pyrrhula pyrrhula*). Two other cavities situated not far from here, **Gumbes B** and **Gumbes C**, situated also on the north coast of the island, offer two more reduced assemblages with no irruptive species.

## RESULTS

The cooling episodes in the northern hemisphere recorded until now have been noted before in high latitudes rather than in low ones. Thus, the temperatures fell in Greenland and Iceland around 250 and 150 years, respectively, before those in Europe (Dansgaard *et al.*, 1975; Burton, 1995). It is probable that short-term climatic deteriorations were noted only in high latitudes, having no consequences in the climatic conditions in middle latitudes, although it may be assumed that some of such events should lead to movements of birds southwards up to refugia in the MR.

Table 3 shows that the first record of irruptive species from the north of Eurasia in the MR occurs near 1 Ma (**Victoria** and **Dursunlu**), in approximate coincidence with the Galerian mammal pulse. From this time up to the end of the Middle Pleistocene, at least, the inner part of the northern Iberian Peninsula had tempered conditions of Eurosiberian type (**Valdegoba**, **Elefante**, **Dolina** and **Galería**). On the contrary, the eastern part held a Mediterranean climate during the all of the Pleistocene, with the exception of occasional enlargements of the Eurosiberian area near the Pyrenees (Gravettian layers from **Arbreda**). Therefore, the climate in Iberia was in general fresher and considerably moister than it is today.

The irruption of northern species in the MR is constantly recorded in the uppermost layers of the Lower Pleistocene (**Huésar 1** and layer

TABLE 3

List of localities arranged by the presence of irruptive Eurosiberian species and the group of grouses, Pygmy owl and Tengmalm's owl (see Appendix 2). Localities from islands and Middle East are underlined.

6 from **Dolina**) and during the Middle Pleistocene, with the exception of CG sediments from **Castiglione 3** (Corsica) and **Áridos 1** (in the middle of Iberia). The MR seems to have disappeared during this time from the south of France, and to be restricted to south half of the western peninsulas and the islands. We lack data for this period from the east of the MR.

The Mousterian period spread out the Eemian and a large part of the Würmian phases

(OIS 3-5). Thus, these follows a succession of shifts in the climatic conditions in the northern hemisphere. The respective positions of some of the localities from this span of time on the chronological Table 2 are particularly uncertain. Some northern irruptions are clearly recorded (**Valdegoba**, layers K and M from **Gorham**, and **Carnello**) and it seems also that the paleornithocaenoses from the middle of Italy were quite different from those from the south.

During the Upper Paleolithic the Eurosiberian area extended to inner Iberia (**Jarama II**), southern France (**Bois-des-Brousses** and **Salpêtrière**), northern Italy (**Arene Candide** and **Fumane**), Adriatic coast (**Šandalja I** and **Šandalja II**) and northern of Balkan Peninsula (layer 3a from **Temnata**, **Trebački**, **Kozarnika** and **Razhishkata**).

## CONCLUSIONS

The Mediterranean extension during the Quaternary reached out more to the western part than to the east, as happens at present. It seems that the Mediterranean conditions never reached the territory of current Bulgaria, although the fossil locations of that area are situated at lower latitudes than the locations from the south of France and many from Italy and Iberia. Some northern irruptive species, but the group of grouse and Pygmy and Tengmalm's Owls, appear on islands (**Coscia**, **Cova Nova**, **Sicily Faunal Complex**, **Liko**, **Pedrera de S'Onix**) and in the Middle East (**Ohalo 2**). The reason for their absence it is not the geographical barrier of the Mediterranean sea (at least for owls), neither the reduced time span of cool phases, but the unsuitable climatic conditions for these species.

There are sufficient data to assume that the geographical boundaries of avian species have changed several times during the Quaternary. Moreover, it may be accepted that some of these changes were not caused directly by climatic circumstances. As can be observed today, increasing individuals of some northern species lead to quick dispersal movements southwards. It is likely that icecap regressions created suitable conditions for demographic explosions, and some of such events could increase the size of populations to magnitudes unmatched by historic observations.

Some of the fossil locations in the south of France and northern Italy (**Arene Candide**, **Bois-des-Brousses**, **La Fage**, **Fontéchevade**, **Lazaret**, **Mas-d'Azil**, **Orgnac 3**, **Romains** and **Salpêtrière**) point to several displacements of characteristic Eurosiberian low dispersive taxa to the MR during the cool phases, following the shifts of climatic and environmental conditions southwards (Table 3). The large record of the genus *Loxia* (a group of birds specialized

in feeding on seed-cones) in southern France and northern Italian localities (Tyrberg, 1991b; see Table 1), implies the existence of at least some phases, particularly during the Upper Pleistocene, with climatic conditions moist enough to permit the spreading of conifer (most probably of pine) forests. The Mediterranean islands, as well as Iberia and the south of the Italian Peninsula, were excluded from this phenomenon and maintained a rather steady paleoecological condition.

There is a very scarce fossil record of irruptive species in the MR during upper Pliocene and early lower Pleistocene. During this span of time, cold pulses only became apparent in the arrival of wintering species into the MR. This fact is unknown until this date, and is firstly observed at **Higueruelas**, which may be considered as the first known avian fossil site of the Quaternary in the Iberian Peninsula. From the Middle Pleistocene onwards, the succession of stadials and interstadials in Europe caused two patterns of avian distribution: a) north and central Europe were severely affected by climatic changes and extensions of the ice cap, which probably led to habitat destruction and latitudinal displacements following distributions in east-west belts (Made, 1992), and b) the MR —at times, only a part of its current extension— supported a Mediterranean ornithofauna during the whole of this time.

In Quaternary fossil localities from the MR no ornithocaenoses have been found with the same taxonomic composition as those existing at present time in northern Eurasia. A number of outcrops that encompass the fossil record of a great part of the Pleistocene points to the irruption of species from northern Europe into the Mediterranean avifaunas. This fact does not imply that the climatic conditions in the Mediterranean region were similar to those in the north of the continent. On the north face of the Mediterranean Sea tempered conditions stayed more or less constant throughout all the Pleistocene. In the south of Europe, not only the Mediterranean region acted like a refuge from the end of the Lower Pleistocene onwards for species that in the interstages occupied more northern territories, but also did so in other zones adjacent to the south of Europe. During the coldest periods MR diminished, although the southern halves of Italy and Iberia, as well as the eastern coast of the latter, were always do-

minated by Mediterranean faunas. Some species currently characteristic of the MR shared the same habitats in a part of northern Iberia, southern France, northern Italy and most of the Balkan Peninsula with species today typical of the Eurosiberian region of Europe.

**ACKNOWLEDGEMENTS.**—I would like to thank to J. A. Alcover and M. Elorza for their valuable comments on the manuscript and to M. Martínón, A. Patterson and J. J. Sanz for his technical assistance. The final phase of this study has relied on the economic support of the European Union Interregional III-B Medocc Project PALAEOMED.

The scientific activity of **Antonio Sánchez** is focussed on the paleornithology, in particular, on the taxonomy, distribution and ecology of Tertiary and Quaternary birds from the Iberian Peninsula, as well as on the climatic changes during the Quaternary. Recently, he has also begun to work in the Canary Islands. He is a member of some archeo-paleontological and neontological teams.

#### APPENDIX 1

Lists of fossil taxa from Mediterranean localities of the Quaternary. The localities are arranged in alphabetical order. Irruptive species for each locality, following the criterium of area of irruption (Appendix 2), are in bold. The group of Pygmy-Tengmalm's owl-grouses (see «areas of irruption» in Appendix 2) is underlined. \* = nowadays survivors in the east part of the region when recorded in the west area. ? = uncertain identification.

[*Lista de especies fósiles de las localidades del Mediterráneo en el Cuaternario. Las localidades están ordenadas alfabéticamente. Especies irruptivas para cada localidad, según el criterio del Apéndice 2 se marcan en negrita. El grupo de los tetraónidos, Mochuelo Alpino y Boreal (ver Apéndice 2) están subrayados. \* = supervivientes hoy día en la parte este de la región, cuando fueron registrados en la parte oeste. ? = Identificación dudosa.*]

## APPENDIX 2

Northern irruptive species in the Mediterranean region during the Quaternary. Current distributions after Cramp (1998).

[Especies nórdicas irruptivas en la región mediterránea durante el Cuaternario. Los datos de distribución actual se han tomado de Cramp (1998).]

Species [Especie]	Current European distribution [Distribución europea actual]	Areas of irruption [Área de irrupción]	Direction of movements [Dirección de los movimientos]
<i>Cygnus olor</i>	Resident in Europe from France east to Black sea. Wintering and resident in zones of southern Italy, Balkans and Anatolia.	Irruptive species in the islands, Iberia and part of Italy	Movements to south and west.
<i>Cygnus cygnus</i>	Winters in north and central Europe, Adriatic coast, southern Balkans, Black sea and southern Anatolia.	Irruptive species in the islands, Iberia and Italy.	Movements to south and west.
<i>Cygnus columbianus</i>	Winters in coasts of British islands, from Germany west to north France, and in inland points to Azure coast.	Irruptive in the whole Mediterranean region, except in Azure and Adriatic coasts.	Movements to south.

<i>Anser brachyrhynchus</i>	Winters in British islands and north Germany.	Irruptive in the whole Mediterranean region.	Movements to south.
<i>Branta bernicla</i>	Winters in coasts from Denmark to west France.	Irruptive in the whole Mediterranean region.	Movements to south.
<i>Branta leucopsis</i>	Winters in British islands and north Germany.	Irruptive in the whole Mediterranean region.	Movements to south.
<i>Aythya marila</i>	Winters in coasts of north Europe, Adriatic and Black sea, also in points of central Europe.	Irruptive in the whole Mediterranean region, except in Adriatic coasts.	Movements to south.
<i>Melanitta fusca</i>	Winters in Atlantic coasts of Europe, in north-west Mediterranean coasts and in Black sea.	Irruptive in the whole Mediterranean region, except in north Adriatic coast, and from north Italy west to coasts of northern half of Iberia.	Movements to south.
<i>Melanitta nigra</i>	Winters in Atlantic and Baltic coasts from Skandinavia to Mauritania, also in coasts of Iberia, south France and north Italy.	Irruptive in the islands and south Italy to east.	Movements to south and west.
<i>Bucephala clangula</i>	Winters in north Europe, inland points, Balkan peninsula, Anatolia, Azure and Adriatic coasts.	Irruptive species in the islands, Iberia and Greece.	Movements to south and west.
<i>Somateria mollissima</i>	Resident and wintering in Atlantic coasts of north and central Europe.	Irruptive in the whole Mediterranean region.	Movements to south.
<i>Clangula hyemalis</i>	Winters in coasts of north, south France and north Italy.	Irruptive in the whole Mediterranean region, except in north Italy and south France.	Movements to south.
<i>Mergus merganser</i>	Winters in north Europe, inland points, Adriatic coasts, northern Balkan peninsula and points of Anatolia.	Irruptive in west Mediterranean area, islands, southern Balkanic peninsula and Anatolia.	Movements to south and west.
<i>Mergus albellus</i>	Winters in coasts of central and western Europe, inland points, Adriatic coasts, northern Balkan peninsula and points of Anatolia.	Irruptive in west Mediterranean area, islands, southern Balkanic peninsula.	Movements to south and west.
<i>Buteo lagopus</i>	Winters in north, central and east Europe, in Balkan peninsula and points of northern Anatolia.	Irruptive in west Mediterranean area, islands, southern Balkanic peninsula and Anatolia.	Movements to south and west.
<i>Gallinago media</i>	Breeds in North and Eastern Europe.	Irruptive in the whole Mediterranean region.	Movements to south and west.
<i>Nyctea scandiaca</i>	North Eurasia.	Irruptive in the whole Mediterranean region.	Movements to south.
<i>Surnia ulula</i>	Resident in northern Eurasia.	Irruptive in the whole Mediterranean region.	Movements to south.
<i>Aegolius funereus</i>	Resident in mountains and in the taiga.	Irruptive in the islands, Iberia, Italy and southern Anatolia.	Movements to south and west.
<i>Eremophila alpestris</i>	Resident in Balkan peninsula, Anatolia and Atlas. Wintering species in northern and eastern Europe.	Irruptive in islands and western Mediterranean region.	Movements to south and west.
<i>Carpodacus erythrinus</i>	Breeding in north and east Europe, in points of central Europe and Anatolia.	Irruptive in the whole Mediterranean region except in Anatolia.	Movements to south and west.

<i>Plectrophenax nivalis</i>	Winter species in north, centre and east of Europe. Also in Atlantic coasts of France and northern coasts of Iberia.	Irruptive in the whole Mediterranean region.	Movements to south.
<i>Pinicola enucleator</i>	Resident and wintering species from Scandinavia to the east.	Irruptive in the whole Mediterranean region.	Movements to south.
<i>Loxia pytyopsittacus</i>	Resident in Scandinavia and in the north of Eastern Europe.	Irruptive in the whole Mediterranean region.	Movements to south.
<i>Loxia leucoptera</i>	Resident in the taiga belt, from Eastern Europe to the east.	Irruptive in the whole Mediterranean region.	Movements to south.
<i>Pyrrhula pyrrhula</i>	Resident and wintering species in the whole of Europe, except two southern thirds of Iberia, south of Greece, south of Anatolia and in the mediterranean islands.	Irruptive in the islands and southern Iberia, Greece and Anatolia.	Movements to south.
<i>Bombycilla garrulus</i>	Winters in North, centre and east of Europe. Reaches the Balkan mountains.	Irruptive in the whole region, except in the north of the Balkanic peninsula.	Movements to south.
<i>Carduelis flammea</i>	Resident in north and central Europe. Winters from France to the east.	Irruptive in the whole Mediterranean region, except in north Iberia, France and north Italy.	Movements to south.

## APPENDIX 3

Nowadays surviving species in the east part of the Mediterranean region, with fossil record in the west Mediterranean area during the Quaternary. Current distributions after Cramp (1998).

[*Actuales especies supervivientes en la parte este de la región del Mediterráneo, con fósiles registrados en el área del oeste del Mediterráneo durante el Cuaternario. Los datos de distribución actual se han tomado de Cramp (1998).]*

Species [Especie]	Current European distribution [Distribución europea actual]	Highlighted in Appendix 1 when appeared in localities [Subrayado en el Apéndice 1 cuando apareció en alguna localidad]
<i>Anser erythropus</i>	Breeding species in north Eurasia. It winters in Balkan peninsula and coast of Black sea.	From Italy west to Iberia.
<i>Haliaeetus albicilla</i>	Resident and wintering species in north and east Europe, in zones of the Balkans and Anatolia.	From north Italy (also Corsica and Sardinia) west to Iberia.
<i>Circus macrourus</i>	Breeds north Black sea. Winters in east Mediterranean region.	From north Italy (also Corsica and Sardinia) west to Iberia.
<i>Luscinia luscinia</i>	Breeds in eastern Europe to east. Vagrant in Balkans and Anatolia.	From the west of the MR.
<i>Emberiza melanocephala</i>	Breeds in Italy, Balkan peninsula and Anatolia.	From western islands (from Corsica and Sardinia), southern France and Iberia.
